In the French West Indies, chlordecone (CLD), an organochlorine pesticide, which is highly persistent in the environment, was applied in banana plantations from 1972 to 1993 against the banana weevil Cosmolites sordidus. Pollution surveys conducted in 2001 by the French Department of Health revealed the presence of chlordecone in soils, rivers, springs over large areas in Guadeloupe and Martinique islands. Contamination of drinking water, food crops, aquatic species by CLD has been observed as well as its presence in the blood of men, pregnant women and newborns. There is therefore a large social concern about the extent and evolution of CLD pollution in the French West Indies and its impact on human health and ecosystems. From 2008 to 2012 a multidisciplinary project CHLORDEXCO took place to study the CLD fate in water, soils and the contamination characteristics of aquatic species and food crops. Here, we summarize results obtained on the processes controlling the spatial and temporal patterns of soil and water contamination at the scale of the banana cropping area in Guadeloupe and of the Perou catchment.

The Chlordecone crisis and the CHLORDEXCO Project

The soils and their contamination level

### Contamination of percolation water

Percolation experiments on undisturbed soil columns from contaminated areas showed that CLD concentration in percolated water varied little (3 to 10 μg/L) and were of same magnitude for andosols and nitosols although their CLD stocks, sorption properties and hydrodynamic behaviours differed strongly. Intense macropore flow in the andosols and classical Darcan flow in nitosol is observed. Transport modelling is currently under way for elucidating this observation.

### The main soils in the contaminated areas are andosols, nitosols and ferralsols

They formed from the weathering of volcanic ashes. They have a high organic carbon content that varies in part according to the altitude. They also have high content of secondary minerals, allophane for andosols and halloysite for nitosols and ferralsols.

### Contamination features of rivers

At the outlet of the 12.6 km² Perou catchment in Guadeloupe, contamination of surface waters was permanent with CLD concentrations one order of magnitude less than in percolation water. As can be seen on the figure, CLD concentrations decreased when discharge increased. This is due to dilution effects caused by storm water stemming mainly from uncontaminated uphill areas. Thus, CLD concentrations were highest in base flow indicating that the main pathways of CLD to surface waters is by percolation and groundwater flow.

### Conclusions

Contamination of soil and water in the banana cropped areas of the French West Indies is general and permanent. If no soil remediation strategies can be elaborated this severe environmental contamination will persist for centuries as estimated by Cabidoche et al. (2009). Since CLD propagates mainly by percolation through the soils and by subsurface flow, buffer strips, usually recommended in many regions to limit the pollution of water by pesticides, will not be useful.
