Introduction

Studying natural populations in their habitat can prove difficult using traditional methods such as mark-recapture and radiotelemetry (Clutton-Brock and Lukas 2012). This is particularly true when studying the dispersal habits of small, highly mobile and nocturnal animals such as bats. Furthermore, these methods provide estimates of individual mobility and dispersal, but not of their effective rate at the population level (Prugnolle and de Meeûs 2002). In contrast, genetic methods that allow inferring the distribution of alleles across populations can provide estimates of gene flow, and thus information on the reproductive

Abstract

For elusive mammals like bats, colonization of new areas and colony formation are poorly understood, as is their relationship with the genetic structure of populations. Understanding dispersal and group formation behaviors is critical not only for a better comprehension of mammalian social dynamics, but also for guiding conservation efforts of rare and endangered species. Using nuclear and mitochondrial markers, we studied patterns of genetic diversity and differentiation among and within breeding colonies of giant noctule bats (*Nyctalus lasiopterus*), their relation to a new colony still in formation, and the impact of this ongoing process on the regionwide genetic makeup. Nuclear differentiation among colonies was relatively low and mostly nonsignificant. Mitochondrial variation followed this pattern, contrasting with findings for other temperate bat species. Our results suggest that this may indicate a recent population expansion. On average, female giant noctules were not more closely related to other colony members than to foreign individuals. This was also true for members of the newly forming colony and those of another, older group sampled shortly after its formation, suggesting that contrary to findings for other temperate bats, giant noctule colonies are not founded by relatives. However, mother–daughter pairs were found in the same populations more often than expected under random dispersal. Given this indication of philopatry, the lack of mitochondrial differentiation among most colonies in the region is probably due to the combination of a recent population expansion and group formation events.

success of migrating individuals (Wright 1943; Slatkin 1987). The genetic structure of natural populations can result from a number of interacting factors, such as recent history, dispersal, mating system and group formation (Chesser 1991; Storz 1999; Parreira and Chikhi 2015). Dispersal ability in particular has been shown to be negatively correlated with genetic differentiation across a range of taxa (e.g., plants, Govindaraju 1988; mammals, Bohonak 1999), including temperate bats, where genetic population structure correlates negatively with the extent of migration (Moussy et al. 2013; Burns and Broders 2014).

The formation of a new colony or social group is a rarely witnessed process that is particularly interesting for

its effect on regionwide genetic variation and for providing information about the underlying social dynamics. Where groups consist of philopatric adults, the formation of a new group is usually the result of group fission (Alberts and Altmann 1995; Hoogland 1995; Thierry 2007; Kerth 2008; Armitage *et al.* 2011). However, the level of kinship among the members of the resulting groups varies across species. While in Savannah baboons (*Papio cynocephalus*) social bonds can supersede kin relations in the choice between emerging groups (Van Horn *et al.* 2007), for a range of other primate species (Van Horn *et al.* 2007; Snyder-Mackler *et al.* 2014), as well as African elephants (*Loxodonta africana*, Archie *et al.* 2006), hyenas (*Crocutta crocutta*, Holekamp *et al.* 1993) and yellow-bellied marmots (*Marmota flaviventris*, Armitage 1987), females choose to remain or move together with close kin. The latter has also been documented for big brown bats, *Eptesicus fuscus*, in which average pairwise relatedness was higher than expected among individuals of three of five matriline following the formation of a new group (Metheny *et al.* 2008). Previous studies had found little or no correlation between the degree of association and relatedness levels among members of bat maternity colonies, including in this particular species (Kerth and König 1999; Metheny *et al.* 2007). These estimates had, however, been obtained from established colonies. During colonization, higher levels of relatedness would likely facilitate cooperative behaviors, counterbalancing the increased risk incurred (Greenwood 1980). Nevertheless, the structure and relationships within any group will be shaped by the composition of its founders, socially as well as genetically.

The giant noctule, *Nyctalus lasiopterus*, with a wingspan of up to 45 cm and weighing around 50 g, is the largest European bat species (Ibáñez *et al.* 2004; Fig. 1). It is also one of the rarest, with only a few known breeding colonies in Spain, Hungary, and France (Ibáñez *et al.* 2004; Estók 2007; Hutson *et al.* 2008; Dubourg-Savage *et al.* 2013). A tree-roosting species, the giant noctule has a patchy circum-Mediterranean distribution throughout southern Europe (Iberia, France, Italy, the Balkans and Greece), North Africa, and Anatolia. The species' range also extends into the Caucasus, Iran, Kazakhstan, and the Urals (Ibáñez *et al.* 2004). The demographic dynamics observed in the Iberian Peninsula (Ibáñez *et al.* 2009) indicate that, similar to other temperate bats, giant noctule bats segregate sexually during spring and summer to form breeding colonies (Bradbury 1977; McCracken and Wilkinson 2000). These aggregations of giant noctule females form fission–fusion societies akin to those described for other temperate forest bats (Kerth and König 1999; Willis and Brigham 2004; Patriquin *et al.* 2013) in which frequent roost changes result in

nonrandom associations between colony members (Popalisseanu *et al.* 2008). The benefits of this social system and the factors underlying the individual decisions behind it are still under debate (Aureli *et al.* 2008; Sueur *et al.* 2011).

Colonization of new areas and the formation of new colonies are rare events that have seldom been described in bats, and on only one occasion has colonization been studied in detail from a genetic perspective (*Eptesicus fuscus*, Metheny *et al.* 2008). As part of a long-term study of giant noctule populations in southwestern Andalusia, Spain, we examined the influence of genetic relatedness on the formation of a new colony in Doñana National Park prior to 2007 and after 2010, following a temporary, unexplained 3-year abandonment. We sampled individuals regularly roosting in this new colony, in addition to three stable breeding colonies in the region. Using both nuclear and mitochondrial markers, we assessed genetic population structure and levels of genetic relatedness within colonies. To test the hypothesis that the colonizer group was kin-based, that is, that the foundation of this new group was the result of a joint movement of related females, we first determined whether among-group genetic variance had increased after the establishment of this new colony. Subsequently, we estimated genetically inferred relatedness and putative relations among individuals within colonies and within matriline. We predicted higher levels of relatedness among colonizing females in Doñana National Park than expected by chance. Likewise, if related females moved together, we expected to find higher levels of average pairwise relatedness among females of the same matriline in the new group when compared to females carrying the same haplotypes in other colonies.

We discuss the implications of our findings with regard to the social habits of giant noctules and their demographic history in the region and, in a more general context, as to how they advance our understanding of mammalian social structure and the role played by kinship in the formation of new colonies.

Materials and Methods

Study populations and sampling

We sampled a total of 215 individuals present in four maternity colonies in southern Andalusia, Spain. The breeding colony in Doñana National Park (DNP) is located around a group of bat boxes in a small stand of mainly Eucalyptus trees near the marshes at the mouth of the Guadalquivir River (36.99° N, 6.44° W). Two breeding colonies of *N. lasiopterus* were recently reported from southwestern Andalusia (Ibáñez *et al.* 2009; Fig. 2): one in large, old plane trees (*Platanus* sp.) within “Maria Luisa

Figure 1. Giant noctule bat, *Nyctalus lasiopterus*, as it leaves the roost at dusk in the newly forming colony in Doñana National Park. Photo: Jens Rydell.

Park” (MLP) in the city of Seville (37.37° N, 5.59° W). This was the larger of the two colonies, with an estimated 500 bats roosting there in 2007 (Popa-Lisseanu et al. 2008). The other colony occupied a group of palm trees (*Washingtonia* sp.) located in the gardens of the zoo of Jerez de la Frontera (ZJF; 36.70° N, 6.15° W); this colony had an estimated population of 100–150 females. In contrast to these seminatural colonies, the fourth population is found in a large natural Mediterranean mixed oak forest in “Los Alcornocales Natural Park” (ANP) around 100–150 km southeast of Seville (36.31° N, 5.44° W) and has an estimated size of several thousand individuals that were sampled at different localities.

Samples consisted of wing punch biopsies (Worthington Wilmer and Barratt 1996) stored in 70% ethanol. We analyzed 84 samples from MLP, 52 from ANP and 32 individuals from ZJF. A total of 47 individuals were sampled from the newly forming colony in DNP. This data set was split into: (1) the Doñana “original” colonizing group (D_O ; $N = 23$), consisting of samples collected between 2003 and 2005; and (2) the Doñana “recolonization” group (D_R ; $N = 24$), sampled after the yet unexplained three-year breakdown (2007–2009), during the subsequent recolonization process from 2010 to 2013. For both D_O and D_R , we selected only females that were registered breeding in the colony during more than 1 year.

Molecular markers

Total genomic DNA was extracted from wing punches using a modified salt-based protocol (Aljanabi and Martinez 1997). The two hypervariable domains (HVI and HVII) of the mitochondrial control region were PCR-amplified using primers L15926 (Kocher et al. 1989) and CSBF-R (Wilkinson and Chapman 1991) for HVI, and

L16517 (Fumagalli et al. 1996) and H607 (Worthington Wilmer et al. 1994) for HVII (forward and reverse primers, respectively). Sequences were aligned, visually inspected for ambiguities, and edited by hand using Sequencher v 4.9 (Gene Codes Corp., Ann Arbor, MI). The final sequences were cropped to a length of 437 bp for HVI (including the initial sequence and first repeat of the HVI region as well as flanking tRNA genes and part of the *cyt b* gene) and 397 bp for HVII.

All individuals were additionally genotyped at 11 nuclear microsatellite loci. As no specific microsatellites yet existed for *N. lasiopterus*, annealing temperatures and PCR mix concentrations were optimized for eight markers developed for *N. leisleri* (Nle 2,3, and 6–11; Boston et al. 2008), one developed for *Eptesicus fuscus* (EF4, Vonhof et al. 2002) and two developed for *Nyctalus noctula* (P20, P217; Mayer 1997). All were tested in muscle tissue prior to genotyping. Labelling followed Schuelke’s procedure (2000).

See Appendix S1 for a detailed description of DNA extraction, amplification, sequencing, and microsatellite genotyping.

Data analysis

Mitochondrial DNA

The two mitochondrial fragments were concatenated and the number of haplotypes (h), haplotype diversity (Hd), nucleotide diversity (π), and the number of segregating sites (S) were calculated using DNASP v. 5.10.1 (Rozas 2009). A median-joining network based on haplotypes was constructed using NETWORK (Bandelt et al. 1999). Through analyses of molecular variance (AMOVA, Excoffier et al. 1992), we assessed how genetic variation was partitioned among colonies, whereby we explored different grouping combinations to identify the one that maximized the among-group component of genetic variation. AMOVA was performed using the software ARLEQUIN v. 3.5.1.2 (Excoffier et al. 2005), which was also used to calculate ϕ_{ST} values among colonies.

Microsatellites

All microsatellite loci were tested for genotyping errors using MICROCHECKER v. 2.2.3 (Van Oosterhout et al. 2004). Linkage disequilibrium among markers was assessed using FSTAT v. 2.8.3.2 (Goudet 2001). Identification of loci under selection was performed using the software ARLEQUIN v. 3.5.1.2. Calculations of allele frequencies (including null alleles) across colonies, observed (H_o) and expected (H_e) heterozygosities, as well as deviations from Hardy–Weinberg equilibrium (HWE)

were performed in CERVUS v. 3.0.6 (Kalinowski *et al.* 2007). Allelic richness was assessed using the R package “hierfstat” (Goudet 2005).

Given the recent developments and ongoing debate about the various existing population differentiation measures and their appropriate use (Hedrick 1999; Jost 2008; Heller and Siegismund 2009; Meirmans and Hedrick 2011), we opted to estimate both D_{EST} and F_{ST} , the former for a more robust analysis and as a reference for future studies, the latter to facilitate comparison with results from previous studies. Both measures were calculated using the R package “diveRsity” (Keenan *et al.* 2013). As for mtDNA, partitioning of genetic variation at the nuclear level was assessed with AMOVA in ARLEQUIN 3.5.1.2.

Genetic relatedness

Pairwise and mean relatedness values (R), both among colonies and for matriline (between individuals with shared mitochondrial haplotypes), were estimated using ML-Relate (Kalinowski *et al.* 2006). This software implements a corrected maximum-likelihood approach that allows loci with null alleles to be incorporated into the analysis (Wagner *et al.* 2006). Mother–daughter pairs were identified, allowing not only to determine the number and proportion of close kin ($r > 0.25$) and of mother–daughter pairs within our data set, but also to examine the distribution of these dyads across colonies. Assignments inconsistent with mitochondrial haplotypes were excluded.

For each colony, we estimated the proportion of close associations out of all possible pairs of individuals (% $r > 0.25$), as well as the proportion (%) of females with at least one close relative within the colony.

Results

Genetic diversity

A total of 15 haplotypes were found, which varied on average by only one substitution, comprising a total of 15 polymorphic sites. The two most common haplotypes were present in all colonies (Fig. 3) and together represented 86% of the individuals sampled. The remaining 13 haplotypes were found in two populations at most, six of them being present in only one. Colonies had between 4 and 8 haplotypes (mean $5.6 \pm SD 1.52$). Haplotype diversity ranged from 0.179 to 0.759 (total $H_d = 0.578$, Table 1), being lowest for ZJF and highest for D_O (first colonization attempt of Doñana), followed by ANP (the only two colonies located in a “natural” habitat). The median-joining network showed a star-shaped structure around the two most frequent haplotypes (Fig. 3).

All microsatellite loci were polymorphic, with an average of 12 alleles, and all were in linkage equilibrium. H_o ranged from 0.347 to 0.850 (Table S1). Out of the 11 microsatellites, four (Nle9, Nle11, P20 and P217, see Table S1) deviated significantly from HWE and were excluded from the genetic structure analysis. Selection acting on Nle11 could not be ruled out ($P < 0.05$),

Figure 2. Location of the three maternity colonies and colonization site included in the study, as well as major towns and rivers. Grey areas indicate Natural and National parks of “Los Alcornocales” and “Doñana”, respectively.

variation, whereas this component was maximized when the two colonizer groups were grouped together with MLP and ZJF (II, III; Table 4). Nuclear variation was not affected by the different grouping strategies, with values of the among-group component always below 1% (Table 4).

Relatedness estimates

Mean pairwise relatedness within colonies was very low (0.075 ± 0.10 , Table 5). Average relatedness values within matriline in the different colonies varied considerably but were altogether also low ($0.055 \pm 7e-2$, Table 6), ranging from 0 (D_R , H2) to 0.345 (MLP, H5), although the latter consisted of only two females. Of the four haplotypes found in D_R , one was carried by only one female and two by unrelated females (H2 and H3, Table 6). Finally, average pairwise relatedness among females sharing H1 was low, with only three of its females being closely related ($r > 0.25$, Table 6). The number of females with at least one close relative in the same colony was high (62.5–93%, Table 5). Here, ZJF and ANP presented the lowest averages, 62.5 and 80.8%, respectively. Relationship estimates based on microsatellite data revealed an elevated number of parental associations across all populations that involved approximately half the individuals sampled (57.1%, $N = 215$, Table 5). As many as 72.7% of all paired females originated from the same colony. In MLP, this resulted in 43 of the 84 individuals (51%) roosting with their putative mothers/daughters. In ANP, 13 parental associations (involving 21 females, 40%) were found, while in DNP we only identified four (all within the post-2007 group). No such association was found among individuals from ZJF. As for inferred mother–daughter dyads pairing females from DNP together with females from other colonies, we found five involving females from D_O , and 12 involving females from D_R . Regarding the former, three of five involved females from ANP (the two others assigned to MLP and ZJF), while in the latter, 9 of 12

Table 5. Mean pairwise relatedness R within colonies, percentage of closely related dyads, percentage of females with close relatives within colonies, and number of parental associations per population (n_{par}).

Colony	R (mean \pm SD)	% associations with $r > 0.25$	% females with close relatives	n_{par}
D_O	0.046 (± 0.090)	1.3	83.3	0
D_R	0.040 (± 0.078)	1.0	91.3	4
DNP	0.085 (± 0.109)	9.5	93.6.5	4
MLP	0.059 (± 0.097)	6.6	97.6	39
ANP	0.052 (± 0.091)	6.0	80.8	11
ZJF	0.048 (± 0.076)	3.4	62.5	0
Total	0.059 (± 0.090)	6.1	1	105

dyads involved females from MLP (two involved the same female from ZJF, the last one ANP). The number of mother–daughter pairs was uncorrelated with variation in sampling year for each colony ($R^2 = 0.0$, $P = 0.53$), but increased significantly with the number of samples of each colony ($R^2 = 0.90$, $P = 0.009$).

Discussion

Population structure and recent demographic expansion

We genotyped bats from three consolidated colonies and a recently colonized site (with two colonization events) and assayed variation both at nuclear and mitochondrial loci and levels of differentiation among the colonies. Haplotype diversity was highest in the D_O and ANP colonies, both situated in natural environments, whereas the two other stable colonies are located in urban parks. Mitochondrial differentiation and, to a lesser extent, nuclear differentiation of the ANP colony from the remainder further suggest a certain degree of genetic isolation and, as the former is mainly due to the presence of a private allele carried by 15.4% of its females, philopatry. The lack of any significant

Table 4. AMOVA-estimated variance components among colonies of giant noctule bats in Andalusia, Spain, according to different grouping designs. Contributions of the different variance components are given as percentage of total variation.

differentiation among the remaining sites indicates either a common, relatively recent origin, and/or high levels of gene flow mediated by dispersal in both sexes. Molecular variance analysis of different grouping designs, which returned higher values of among-colony variation when ANP was kept isolated and D_O and D_R were grouped together with MLP and ZJF, further supports this idea. Radiotracking and a few ring-recovery data indicate movements between all the studied colonies, which could help to explain the lack of differentiation between them (Popa-Lisseanu et al. 2009). However, the lack of structure at the mitochondrial level should not be attributed to modern-day dispersal or group formation dynamics alone. The presence of the two most frequent haplotypes in every population and the star-shaped topology of the median-joining network both point to a recent population expansion (Fig. 3). Differences between putative original populations could account for the sharp differences in haplotype diversity found between the first and second colonizer groups. Finally, different group formation processes (dispersal for D_O vs. budding for D_R) could also result in similar differences.

Regional kin structure

We estimated relationships among individuals based on shared nuclear alleles and analyzed the distribution of close kin ($r > 0.25$) and mother–daughter pairs across the region. The number of females with at least one close relative in the same colony was unexpectedly high for some sites, particularly for the colony in the city park of Seville (MLP). However, it is the number of parental associations found within our complete data set and encompassing the whole area studied that stands out the most with 57.1% of parental associations found to be intracolony. The complementary 42.9% of these involved females from separate colonies, suggesting still, relatively frequent movements

and thus significant gene flow between the colonies. A recent study revealed a negative correlation between wing loading, migration tendency, and the magnitude of genetic differentiation among bat populations (Burns and Broders 2014). Our study sites are at most 150 km apart (MLP to ANP), and previous studies have not only indicated that *N. lasiopterus* can undergo long-distance migrations, but have also reported important movements in this particular region (Ibáñez et al. 2009; Popa-Lisseanu et al. 2009). We therefore expected a more even distribution of dyads, reflecting “regional philopatry” (sensu Vonhof et al. 2008). Instead, we found that 33.6% of females (a conservative estimate considering we could not sample all individuals in every colony) stayed in the same colony as their mothers or daughters. While this estimate falls predictably short of that found in colonies of nonmigratory Bechstein’s bats, characterized by strict female philopatry (72%; Kerth et al. 2002), it is higher than what was reported in big brown bats (9%; Vonhof et al. 2008), a species with an estimated migratory range of up to 288 km between maternity and winter roosts (Mills et al. 1975).

Colonization of Doñana National Park

We studied two consecutive colonization attempts of DNP by giant noctules in relation to the three closest known colonies of the species. We found considerable colocalization of female relatives, pointing to a high degree of philopatry and indicating that reported movements do not necessarily result in stable relocations. The lack of differentiation among all the colonies (except for ANP) could be due to the fact that these are too young for any differentiation to become apparent at the mitochondrial level. The formation of new groups or colonies involves the sampling of alleles from one or more parent groups. The degree to which founding individuals are related to one

another will influence the genetic variation of the newly formed groups, and consequently the amount of among-group variation at the population level (Storz 1999). If the formation of the new colony in DNP was the result of random dispersal of females from different nearby colonies, following Slatkin's migrant-pool model (Slatkin 1977), we would expect the lack of genetic structure we observed. In that case, there may not have been sufficient time for philopatry to counteract this effect. On the other hand, if the new colony was the result of fissioning of closely related females from another colony (propagule-pool model, Slatkin 1977), the level of genetic relatedness among females of the new group would be higher and the genetic sampling less representative of the whole, increasing among-group variation. It is important to note that no ringed females (sampled or not) from the initial colonization were ever reported back in the new DNP recolonization group. While the recolonizers of DNP harbor fewer haplotypes than its previous settlers (4 and 8, respectively), an analysis of molecular variance failed to detect an increase in among-colony genetic variation after the creation of either group. The most parsimonious conclusion is that the Doñana, Seville, and Jerez colonies are relatively recent and related. It is likely that they are the result of an expansion of the natural population of *N. lasiopterus* living in the large area of *Quercus* spp. forest in Cadiz Province, encompassing most of Alcornocales Natural Park (ANP). This hypothesis is in agreement with the star-like distribution of the haplotype network. Nevertheless, the presence of private haplotypes in all new colonies points to the possibility of genetic additions from other colonies (or regions) apart from an ANP source. In summary, it seems likely that the lack of structure found is mostly due to recent demographic changes, not yet counteracted by the structuring effect of philopatry.

The only previous genetic analysis of the formation of a new group in temperate bats is a study of the tree-roosting big brown bat (*E. fuscus*) by Metheny *et al.* (2008). The studied colony fissioned, one group moving to a previously uninhabited area 7 km away from the original colony (Metheny *et al.* 2008). The authors found higher levels of relatedness in the seceding group than in the prefission one, suggesting that females from matrilineal lines with higher relatedness levels had moved together, a pattern that was interpreted as ensuring the cooperative behaviors needed for group formation (Metheny *et al.* 2008). We found that average pairwise relatedness within the colonizer groups was nearly twice that of established colonies (Table 6) and four mother–daughter pairs were identified within D_R , indicating that colony formation in giant noctules does to some extent benefit from the coordinated move of related females. However, the presence of multiple haplotypes among the colonizers, leaving

regional genetic structure unaffected, and the generally low pairwise relatedness values indicate a more complex scenario. The question remains open as to which individual-based considerations – such as proximity to foraging areas, temperature conditions, presence of kin or social partners – underlie the formation of a new group in this species. The presence of unrelated individuals can either be explained by independent simultaneous movements of females, or cooperation and information sharing. Given their flight range (females can cover distances exceeding those between colonies during nightly foraging bouts – Ibáñez *et al.* 2009; Popa-Lisseanu *et al.* 2009), it is reasonable to assume that independent discovery of roosts available at the new site by several females would have been quick. If the site's advantages were clear (*i.e.*, unoccupied bat boxes, overcrowding of the remaining sites, proximity to Doñana's insect-rich foraging grounds), the arrival by unrelated females might have simply involved their individual choice to move, its speed giving the appearance of one coordinated movement. On the other hand, kinship-independent information transfer about novel roosts and their relative quality has been reported in Bechstein's bats (Kerth *et al.* 2002; Kerth and Petit 2005) and could also, if confirmed in giant noctules, explain the simultaneous movement of several females to a newly available area. Our own analysis of parent–offspring dyads involving individuals from both the original and recolonizing groups of Doñana identified an additional six dyads (42% more) in the latter group, the majority of these (9/11) related to females from Seville. Together with the small number of haplotypes in that group and the clustering with MLP in the AMOVA, our results seem to point to a common origin, in support of the latter hypothesis. However, because we are lacking exact information on the initial steps of the colonization, as well as on interactions among the colonizers prior to their movement, the dynamics of this process cannot yet be fully understood. It is possible that for a species of long-range fliers the decision to switch between colonies within this range is simply not under significant energetic restraints. On the contrary, at least three of the studied colonies (including the one in DNP) may be acting as a large social unit with frequent exchanges between them, despite their distance and the region's habitat heterogeneity (Popa-Lisseanu *et al.* 2009).

It is likely that the process of colonization is not a fixed species characteristic, but rather a plastic behavior molded by social and ecological factors. Group fission along matrilineal lines documented for *E. fuscus* by Metheny *et al.* (2008) is probably not the norm, even within the same species, as suggested by the lack of genetic structure among the populations of big brown bats studied by Vonhof *et al.* (2008). Even though the existence of a fine-scale genetic

structure has been reported in many mammalian societies (Altmann et al. 1996; Ratnayeke et al. 2002; Nussey et al. 2005; Robinson et al. 2012), suggesting that kinship plays an important role in group choice during group fission, more research is needed to understand the relative roles played by kinship and social bonds (see also Lukas et al. 2005). A predominance of the latter would explain the divergent results obtained across different bat species, in which average relatedness within social groups is remarkably low (Castella et al. 2001; Kerth et al. 2002; present study). We found evidence of philopatry, as well as of cooperation among kin during the formation of new breeding colonies in *N. lasiopterus*. However, the lack of suitable roosting grounds available in this heavily deforested region (Valbuena-Carabaña et al. 2010) is likely to play a strong role, and could impact the decision to remain with kin (Russo et al. 2004). Moreover, the crash of the D₀ population in 2007 remains unexplained, but highlights the fragility of any colonization process.

In summary, further investigations into these unique populations will be essential to better understand bat social dynamics as well as help to efficiently design programs for the preservation of this rare and endangered species.

Acknowledgments

J. Noguera and C. Ruiz helped collecting bat samples. We particularly thank J. L. García-Mudarra and J. M. Arroyos-Salas for valuable advice and their technical insight, and M. Tavares-Queiroga for her creativity in producing the map. We also acknowledge the staff of the Servicio de Parques y Jardines de Sevilla, the Zoo-Botánico of Jerez de la Frontera, La Almoraima SA, and Los Alcornocales Natural Park for their help and continuous support of our research. Logistical support was provided by the Laboratorio de Ecología Molecular, Estación Biológica de Doñana, CSIC (LEM-EBD). The regional government of Andalusia and Doñana National Park provided permits for collecting samples and handling of bats. This study was partially funded by the Spanish MICINN CGL 2009-12393, the PPNN 021/2002 and 1981/2010, and the EBD-Severo Ochoa (SEV-2012-443 0262) projects. JDS would like to acknowledge support from the Erasmus Student Mobility program.

Conflict of Interest

None declared.

Data Accessibility

Mitochondrial DNA sequences have been uploaded to GenBank (Accession numbers: HVI: KX709626 - KX709837,

HVII: KX621557 - KX621770). Microsatellite genotypes, sample ID and location, R scripts for F_{ST} , D_{EST} , and allelic richness calculations were deposited in the Dryad Digital Repository (doi: 10.5061/dryad.rc504).
